Abstract—It is now well understood that the $\ell_1$ minimization algorithm is able to recover sparse signals from incomplete measurements [2], [1], [3] and sharp recoverable sparsity thresholds have also been obtained for the $\ell_1$ minimization algorithm. However, even though iterative reweighted $\ell_1$ minimization algorithms or related algorithms have been empirically observed to boost the recoverable sparsity thresholds for certain types of signals, no rigorous theoretical results have been established to prove this fact. In this paper, we try to provide a theoretical foundation for analyzing the iterative reweighted $\ell_1$ algorithms. In particular, we show that for a nontrivial class of signals, the iterative reweighted $\ell_1$ minimization can indeed deliver recoverable sparsity thresholds larger than that given in [1], [3]. Our results are based on a high-dimensional geometrical analysis (Grassmann angle analysis) of the null-space characterization for $\ell_1$ minimization and weighted $\ell_1$ minimization algorithms.

I. INTRODUCTION

In this paper we are interested in compressed sensing problems. Namely, we would like to find $x$ such that

$$Ax = y$$  

where $A$ is an $m \times n$ ($m < n$) measurement matrix, $y$ is a $m \times 1$ measurement vector and $x$ is an $n \times 1$ unknown vector with only $k$ ($k < m$) nonzero components. We will further assume that the number of the measurements is $m = \delta n$ and the number of the nonzero components of $x$ is $k = \zeta n$, where $0 < \zeta < 1$ and $0 < \delta < 1$ are constants independent of $n$ (clearly, $\delta > \zeta$).

A particular way of solving (1) which has recently generated a large amount of research is called $\ell_1$-optimization (basis pursuit) [2]. It proposes solving the following problem

$$\begin{align*}
\min_{x} & \|x\|_1 \\
\text{subject to} & \ Ax = y.
\end{align*}$$  

Quite remarkably in [2] the authors were able to show if the number of the measurements is $m = \delta n$ and if the matrix $A$ satisfies a special property called the restricted isometry property (RIP), then any unknown vector $x$ with no more than $k = \zeta n$ (where $\zeta$ is an absolute constant which is a function of $\delta$, but independent of $n$, and explicitly bounded in [2]) non-zero elements can be recovered by solving (2). Instead of characterizing the $m \times n$ matrix $A$ through the RIP condition, in [1], [3] the authors assume that $A$ constitutes a $k$-neighborly polytope. It turns out (as shown in [1]) that this characterization of the matrix $A$ is in fact a necessary and sufficient condition for (2) to produce the solution of (1). Furthermore, using the results of [4]/[7]/[8], it can be shown that if the the if the matrix $A$ has i.i.d. zero-mean Gaussian entries with overwhelming probability it also constitutes a $k$-neighborly polytope. The precise relation between $m$ and $k$ in order for this to happen is characterized in [1] as well.

In this paper we will be interested in providing the theoretical guarantees for the emerging iterative reweighted $\ell_1$ algorithms [15]. These algorithms iteratively updated weights for each element of $x$ in the objective function of $\ell_1$ minimization, based on the decoding results from previous iterations. Experiments showed that the iterative reweighted $\ell_1$ algorithms can greatly enhance the recoverable sparsity threshold for certain types of signals, for example, sparse signals with Gaussian entries. However, no rigorous theoretical results have been provided for establishing this phenomenon. To quote from [15], “any result quantifying the improvement of the reweighted algorithm for special classes of sparse or nearly sparse signals would be significant”. In this paper, we try to provide a theoretical foundation for analyzing the iterative reweighted $\ell_1$ algorithms. In particular, we show that for a nontrivial class of signals, (It is worth noting that empirically, the iterative reweighted $\ell_1$ algorithms do not always improve the recoverable sparsity thresholds, for example, they often fail to improve the recoverable sparsity thresholds when the non-zero elements of the signals are “flat” [15]), a modified iterative reweighted $\ell_1$ minimization algorithm can indeed deliver recoverable sparsity thresholds larger than those given in [1], [3] for unweighted $\ell_1$ minimization algorithms. Our results are based on a high-dimensional geometrical analysis (Grassmann angle analysis) of the null-space characterization for $\ell_1$ minimization [11] and weighted $\ell_1$ minimization algorithms [12](relying on oracle prior information). We show that even without oracle prior information, the preceding $\ell_1$ minimization iterations can provide certain information about the support set of the signals and this support set information can be properly taken advantage of to perfectly recover the signals even though the sparsity of the signal $x$ itself is large.

This paper is structured as follows. In Section II, we present the iterative reweighted $\ell_1$ algorithm for analysis. The signal model for $x$ will be given in Section III. In Section IV and Section V, we will show how the iterative reweighted $\ell_1$ minimization algorithm can indeed improve recoverable sparsity thresholds. Numerical results will be given in Section VI.

II. THE MODIFIED ITERATIVE REWEIGHTED $\ell_1$ MINIMIZATION ALGORITHM

Let $w_i^t$, $i = 1, \ldots, n$, denote the weights for the $i$-th element $x_i$ of $x$ in the $t$-th iteration of the iterative reweighted $\ell_1$ minimization algorithm and let $W^t$ be the diagonal matrix with $w_1^t, w_2^t, \ldots, w_n^t$ on the diagonal. In the paper [15], the following iterative reweighted $\ell_1$ minimization algorithm is presented:

Algorithm 1: [15]

1) Set the iteration count $t$ to zero and $w_i^t = 1$, $i = 1, \ldots, n$.

2) Solve the weighted $\ell_1$ minimization problem

$$x^t = \arg \min _{x} \{ ||W^t x||_1 \} \ \text{subject to} \ y = Ax.$$  

$$\begin{align*}
\end{align*}$$
3) Update the weights: for each $i = 1, \ldots, n$,
$$w_{t+1}^i = \frac{1}{|x_i| + \epsilon'},$$
where $\epsilon'$ is a tunable positive number.
4) Terminate on convergence or when $t$ attains a specified maximum number of iterations $t_{\text{max}}$. Otherwise, increment $t$ and go to step 2.

For the sake of tractable analysis, we will give another iterative reweighted $\ell_1$ minimization algorithm, but it still captures the essence of the reweighted $\ell_1$ algorithm presented in [15]. In our modified algorithm, we only do two $\ell_1$ minimization programming iterations, namely we stop at the time index $t = 1$.

Algorithm 2: 1) Set the iteration count $t$ to zero and $w_1^i = 1$, $i = 1, \ldots, n$.
2) Solve the weighted $\ell_1$ minimization problem
$$x^* = \arg\min ||Wx||_1 \quad \text{subject to} \quad y = Ax.$$  
3) Update the weights: find the index set $K' \subset \{1, 2, \ldots, n\}$ which corresponds to the largest $(1 - \epsilon)\rho_F(\delta)\delta n$ elements of $x$ in amplitudes, where $0 < \epsilon < 1$ is a specified parameter and $\rho_F(\delta)$ is the weak threshold for perfect recovery defined in [1] using $\ell_1$ minimization (thus $\zeta = \rho_F(\delta)$ is the weak sparsity threshold). Then assign the weight $W_1 = 1$ to those $w_{1+1}^i$ corresponding to the set $K'$ and assign the weight $W_2 = W$, $W > 1$, to those $w_{1+1}^i$ corresponding to the complementary set $K' = \{1, 2, \ldots, n\} \setminus K'$.
4) Terminate on convergence or when $t = 1$. Otherwise, increment $t$ and go to step 2.

Note that $W$ is a constant that is preset and can be optimized as shown later in this paper. This modified algorithm is certainly different from the algorithm from [15], but the important thing is that both algorithms assign bigger weights to those elements of $x$ which are more likely to be 0.

III. SIGNAL MODEL FOR $x$

In this paper, we consider the following model for the $n$-dimensional sparse signal $x$. First of all, we assume that there exists a set $K \subset \{1, 2, \ldots, n\}$ with cardinality $|K| = (1 - \epsilon)\rho_F(\delta)\delta n$ such that each of the elements of $x$ over the set $K$ is large in amplitude. WLOG, those elements are assumed to be all larger than $a_1 > 0$. For a given signal $x$, one might take such set $K$ to be the set corresponding to the $(1 - \epsilon)\rho_F(\delta)\delta n$ largest elements of $x$ in amplitude.

Secondly, (let $\hat{K} = \{1, 2, \ldots, n\} \setminus K$), we assume that the $\ell_1$ norm of $x$ over the set $\hat{K}$, denoted by $\|x_{\hat{K}}\|_1$, is upper-bounded by $\Delta$, though $\Delta$ is allowed to take a non-diminishing portion of the total $\ell_1$ norm $\|x\|_1$ as $n \to \infty$. We further denote the support set of $x$ as $K_{\text{total}}$ and its complement as $\hat{K}_{\text{total}}$. The sparsity of the signal $x$, namely the total number of nonzero elements in the signal $x$ is then $|K_{\text{total}}| = \hat{K}_{\text{total}} = \xi n$, where $\xi$ can be above the weak sparsity threshold $\zeta = \rho_F(\delta)$ achievable using the $\ell_1$ algorithm. In the following sections, we will show that if certain conditions on $a_1, \Delta$ and the measurement matrix $A$ are satisfied, we will be able to recover perfectly the signal $x$ using Algorithm 2 even though its sparsity level is above the sparsity threshold for $\ell_1$ minimization. Intuitively, this is because the weighted $\ell_1$ minimization puts larger weights on the signal elements which are more likely to be zero, and puts smaller weights on the signal support set, thus promoting sparsity at the right positions. In order to achieve this, we need some prior information about the support set of $x$, which can be obtained from the decoding results in previous iterations. We will first argue that the equal-weighted $\ell_1$ minimization of Algorithm 2 can sometimes provide very good information about the support set of signal $x$.

IV. ESTIMATING THE SUPPORT SET FROM THE $\ell_1$ MINIMIZATION

Since the set $K'$ corresponds to the largest elements in the decoding results of $\ell_1$ minimization, one might guess that most of the elements in $K'$ are also in the support set $K_{\text{total}}$. The goal of this section is to get an upper bound on the cardinality of the set $K_{\text{total}} \cap K'$, namely the number of zero elements of $x$ over the set $K'$. To this end, we will first give the notion of “weak” robustness for the $\ell_1$ minimization.

Let $K$ be fixed and $x_{K}$, the value of $x$ on this set, be also fixed. Then the solution produced by (2), $\hat{x}$, will be called weakly robust if, for some $C > 1$ and all possible $x_{\hat{K}}$, it holds that
$$\|x - \hat{x}\|_K \leq \frac{2C}{C-1} \|x_{\hat{K}}\|_1.$$  

The above “weak” notion of robustness allows us to bound the error $\|x - \hat{x}\|_1$, in the following way. If the matrix $A_K$, obtained by retaining only those columns of $A$ that are indexed by $K$, has full column rank, then the quantity
$$\kappa = \max_{Aw = 0, w \neq 0} \frac{\|w_K\|_1}{\|w_{\hat{K}}\|_1}$$
must be finite ($\kappa < \infty$). In particular, since $x - \hat{x}$ is in the null space of $A$ ($y = Ax = A\hat{x}$), we have
$$\|x - \hat{x}\|_1 = \|x - \hat{x}\|_K + \|x - \hat{x}\|_{\hat{K}} \leq (1 + \kappa)\|x - \hat{x}\|_K \leq \frac{2C(1 + \kappa)}{C-1} \|x_{\hat{K}}\|_1,$$  
thus bounding the recovery error. We can now give necessary and sufficient conditions on the pair $(A, x)$ to satisfy the notion of weak robustness for $\ell_1$ minimization.

**Theorem 1**: For a given $C > 1$, support set $K$, and $x_K$, the solution $\hat{x}$ produced by (2) will be weakly robust if, and only if, $\forall w \in \mathbb{R}^n$ such that $Aw = 0$, we have
$$\|x_K + w_K\|_1 + \|w_{\hat{K}}\|_1 \leq \frac{2C}{C-1} \|x_{\hat{K}}\|_1;$$

**Proof**: Sufficiency: Let $w = \hat{x} - x$, for which $Aw = A(\hat{x} - x) = 0$. Since $\hat{x}$ is the minimum $\ell_1$ norm solution, we have $\|x\|_1 \geq \|\hat{x}\|_1 = \|x+w\|_1$, and therefore $\|x_K\|_1 + \|w_{\hat{K}}\|_1 \leq \|x_{\hat{K}}\|_1$, and hence $\|x_K\|_1 \leq \|x_{\hat{K}}\|_1$. Thus,
$$\|x_K\|_1 - \|x_K + w_K\|_1 \geq \|w_K + x_K\|_1 - \|x_K\|_1 \geq \|w_{\hat{K}}\|_1 - 2\|x_{\hat{K}}\|_1.$$  

But the condition (6) guarantees that
$$\|w_K\|_1 \geq C(\|x_K\|_1 - \|x_K + w_K\|_1),$$
so we have
$$\|w_K\|_1 \leq \frac{2C}{C-1} \|x_{\hat{K}}\|_1,$$
and
$$\|x_K\|_1 - \|x_{\hat{K}}\|_1 \leq \frac{2}{C-1} \|x_{\hat{K}}\|_1;$$
as desired.

Necessity: Since in the above proof of the sufficiency, equalities can be achieved in the triangular inequalities, the condition (6) is also a necessary condition for the weak robustness to hold for every $x$. (Otherwise, for certain $x$’s, there will be $x' = x + w$ with $\|x'\|_1 < 5499$.
\[ \|x\|_1 \] while violating the respective robustness definitions. Also, such \( x' \) can be the solution to (2)).

We should remark (without proof for the interest of space) that for any \( \delta > 0 \), \( 0 < \epsilon < 1 \), let \( |K| = (1 - \epsilon)P_F(\delta)\delta n \), and suppose each element of the measurement matrix \( A \) is sampled from i.i.d. Gaussian distribution, then there exists a constant \( C > 1 \) (as a function of \( \delta \) and \( \epsilon \)), such that the condition (6) is satisfied with overwhelming probability as the problem dimension \( n \to \infty \). At the same time, the parameter \( \kappa \) defined above is upper-bounded by a finite constant (independent of the problem dimension \( n \)) with overwhelming probability as \( n \to \infty \). These claims can be shown by using the Grassmann angle approach for the balancedness property of random linear subspaces in [11]. In the current version of our paper, we would make no attempt to explicitly express the parameters \( C \) and \( \kappa \).

In Algorithm 2, after equal-weighted \( \ell_1 \) minimization, we pick the set \( K' \) corresponding to the \( (1 - \epsilon)P_F(\delta)\delta n \) largest elements in amplitudes from the decoding result \( \hat{x} \) (namely \( x' \) in the algorithm description) and assign the weights \( W_1 = 1 \) to the corresponding elements in the next iteration of reweighted \( \ell_1 \) minimization. Now we can show that an overwhelming portion of the set \( K' \) are also in the support set \( K_{\text{null}} \) of \( x \) if the measurement matrix \( A \) satisfies the specified weak robustness property.

**Theorem 2:** Suppose that we are given a signal vector \( x \in \mathbb{R}^n \) satisfying the signal model defined in Section III. Given \( \delta > 0 \), and a measurement matrix \( A \) which satisfies the weak robustness condition in (6) with its corresponding \( C > 1 \) and \( \kappa < \infty \), then the set \( K' \) generated by the equal-weighted \( \ell_1 \) minimization in Algorithm 2 contains at most \( \frac{2C}{(C-1)^2} \|x_K\|_1 + \frac{2C\kappa}{(C-1)^2} \|x_{\bar{K}}\|_1 \) indices which are outside the support set of signal \( x \).

**Proof:** Since the measurement matrix \( A \) satisfies the weak robustness condition for the set \( K \) and the signal \( x \),

\[
\|x - \hat{x}\|_K \leq \frac{2C}{(C-1)^2} \|x_K\|_1.
\]

By the definition of the \( \kappa < \infty \), namely,

\[
\kappa = \max_{\|W\|_2 = 0, W \neq 0} \|W A x\|_1
\]

we have

\[
\| (x - \hat{x})_{\bar{K}} \|_1 \leq \kappa \| (x - \hat{x})_K \|_1.
\]

Then there are at most \( \frac{2C}{(C-1)^2} \|x_K\|_1 \) indices that are outside the support set of \( x \) but have amplitudes larger than \( \frac{\kappa}{\pi} \) in the corresponding positions of the decoding result \( \hat{x} \) from the equal-weighted \( \ell_1 \) minimization algorithm. This bound follows easily from the facts that all such indices are in the set \( K \) and that \( \| (x - \hat{x})_K \|_1 \leq \frac{2C}{(C-1)^2} \|x_K\|_1 \).

Similarly, there are at most \( \frac{2C\kappa}{(C-1)^2} \|x_{\bar{K}}\|_1 \) indices which are originally in the set \( K \) but now have corresponding amplitudes smaller than \( \frac{\kappa}{\pi} \) in the decoded result \( \hat{x} \) of the equal-weighted \( \ell_1 \) algorithm.

Since the set \( K' \) corresponds to the largest \( (1 - \epsilon)P_F(\delta)\delta n \) elements of the signal \( \hat{x} \), by combining the previous two results, it is not hard to see that the number of indices which are outside the support set of \( x \) but are in the set \( K' \) is no bigger than \( \frac{2C}{(C-1)^2} \|x_K\|_1 + \frac{2C\kappa}{(C-1)^2} \|x_{\bar{K}}\|_1 \).

As we can see, Theorem 2 provides useful information about the support set of the signal \( x \), which can be used in the analysis for the weighted \( \ell_1 \) minimization using the null-space Grassmann Angle analysis approach for weighted \( \ell_1 \) minimization algorithm [12].

\[ \text{V. THE GRASSMANN ANGLE APPROACH FOR THE Reweighted } \ell_1 \text{ MINIMIZATION} \]

In the previous work [12], the authors have shown that by exploiting certain prior information about the original signal, it is possible to extend the threshold of sparsity factor for successful recovery beyond the original bounds of [11], [3]. The authors proposed a nonuniform sparsity model in which the entries of the vector \( x \) can be considered as \( T \) different classes, where in the \( i \)-th class, each entry is (independently from others) nonzero with probability \( P_i \), and zero with probability \( 1 - P_i \). The signals generated based on this model will have around \( n_1P_1 + \cdots + n_TP_T \) nonzero entries with high probability, where \( n_i \) is the size of the \( i \)-th class. Examples of such signals arise in many applications as medical or natural imaging, satellite imaging, DNA micro-arrays, network monitoring and so on. They proved that provided such structural prior information is available about the signal, a proper weighted \( \ell_1 \)-minimization strictly outperforms the regular \( \ell_1 \)-minimization in recovering signals with some fixed average sparsity from under-determined linear i.i.d. Gaussian measurements.

The detailed analysis in [12] is only done for \( T = 2 \), and is based on the high dimensional geometrical interpretations of the constrained weighted \( \ell_1 \)-minimization problem:

\[
\min_{x_{\hat{y}}} \sum_{i=1}^{n} w_i |x_i| \quad \text{(7)}
\]

Let the two classes of entries be denoted by \( K_1 \) and \( K_2 \). Also, due to the partial symmetry, for any suboptimal set of weights \( \{w_1, \ldots, w_n\} \) we have the following

\[
\forall i \in \{1, 2, \ldots, n\} \quad w_i = \begin{cases} W_1 \text{ if } i \in K_1 \\ W_2 \text{ if } i \in K_2 \end{cases}
\]

The following theorem is implicitly proven in [12] and more explicitly stated and proven in [13]

**Theorem 3:** Let \( \gamma_1 = \frac{n_1}{n} \) and \( \gamma_2 = \frac{n_2}{n} \). If \( \gamma_1 \geq \gamma_2 \), \( P_1 \), \( P_2 \), \( W_1 \) and \( W_2 \) are fixed, then there exists a critical threshold \( \delta_c = \delta_c(\gamma_1, \gamma_2, P_1, P_2, \frac{W_2}{W_1}) \), totally computable, such that if \( \delta \geq \delta_c \), then a vector \( x \) generated randomly based on the described nonuniformly sparse model can be recovered from the weighted \( \ell_1 \)-minimization of (7) with probability \( 1 - o(e^{-cn}) \) for some positive constant \( c \).

In [12] and [13], a way for computing \( \delta_c \) is presented which, in the uniform sparse case (e.g. \( \gamma_2 = 0 \)) and equal weights, is consistent with the weak threshold of Donoho and Tanner for almost sure recovery of sparse signals with \( \ell_1 \)-minimization.

In summary, given a certain \( \delta \), the two different weights \( W_1 \) and \( W_2 \) for weighted \( \ell_1 \) minimization, the size of the two weighted blocks, and also the number (or proportion) of nonzero elements inside each weighted block, the results from [12] can determine whether a uniform random measurement matrix will be able to perfectly recover the original signals with overwhelming probability.

Using this framework we can now begin to analyze the performance of the modified re-weighted algorithm of section II. Although we are not directly given any prior information, as in the nonuniform sparse model for instance, about the signal structure, one might hope to infer such information after the first step of the modified re-weighted algorithm. To this end, note that the immediate step in the algorithm after the regular \( \ell_1 \)-minimization is to choose the largest \( (1 - \epsilon)P_F(\delta)\delta n \) entries in absolute value. This is equivalent to splitting the index set of the vector \( x \) to two classes \( K' \) and \( K'' \), where \( K' \) corresponds to the larger entries. We now try to find

5500
a correspondence between this setup and the setup of [12] where sparsity factors on the sets $\mathcal{K}'$ and $\mathcal{K}''$ are known. We claim the following upper bound on the number of nonzero entries of $x$ with index on $\mathcal{K}'$.

**Theorem 4:** There are at least $(1 - \epsilon)\rho_F(\delta)\delta n + \frac{2C(k + 1)\Delta}{(C - 1)n^2}$ nonzero entries in $x$ with index on the set $\mathcal{K}'$.

**Proof:** Directly from Theorem 2 and the fact that $\|x_K\|_1 \leq \Delta$.

The above result simply gives us a lower bound on the sparsity factor (ratio of non-zero elements) in the vector $x_K'$:

$$P_1 \geq 1 - \frac{4C(k + 1)\Delta}{(C - 1)n^2} \rho_F(\delta)\delta n$$

Since we also know the original sparsity of the signal, $|x|_0 \leq k_{total}$, we have the following lower bound on the sparsity factor of the second block of the signal $x_{K''}$:

$$P_2 \leq k_{total} - (1 - \epsilon)\rho_F(\delta)\delta n + \frac{4C(k + 1)\Delta}{(C - 1)n^2}$$

Note that if $a_1$ is large and $1 \gg \frac{\Delta}{\rho_F(\delta)\delta n}$ (Note however, we can let $\Delta$ take a non-diminishing portion of $\|x\|_1$, even though that portion can be very small), then $P_1$ is very close to 1. This means that the original signal is much denser in the block $\mathcal{K}'$ than in the second block $\mathcal{K}''$. Therefore, as in the last step of the modified re-weighted algorithm, we may assign a weight $W_1 = 1$ to all entries of $x$ in $\mathcal{K}'$ and weight $W_2 = W$, $W > 1$ to the entries of $x$ in $\mathcal{K}''$ and perform the weighted $\ell_1$-minimization. The theoretical results of [12], namely Theorem 3 guarantee that as long as $\delta > \delta_0(\gamma_1, \gamma_2, P_1, P_2, \frac{W}{\rho_F(\delta)\delta n})$ then the signal will be recovered with overwhelming probability for large $n$. The numerical examples in the next Section do show that the reweighted $\ell_1$ algorithm can increase the recoverable sparsity threshold, i.e. $P_3 \gamma_1 + P_2 \gamma_2$.

**VI. Numerical Computations on the Bounds**

Using numerical evaluations similar to those in [12], we demonstrate a strict improvement in the sparsity threshold from the weak bound of [1], for which our algorithm is guaranteed to succeed. Let $\delta = 0.555$ and $n^2 = 3$ be fixed, which means that $\zeta = \rho_F(\delta)\delta$ is also given. We set $\epsilon = 0.01$. The sizes of the two classes $\mathcal{K}'$ and $\mathcal{K}''$ would then be $\gamma_1 n = (1 - \epsilon)\zeta n$ and $\gamma_2 n = (1 - \epsilon)\zeta n$ respectively. The sparsity ratios $P_1$ and $P_2$ of course depend on other parameters of the original signal, as is given in equations (8) and (9). For values of $P_1$ close to 1, we search over all pairs of $P_1$ and $P_2$ such that the critical threshold $\delta_0(\gamma_1, \gamma_2, P_1, P_2, \frac{W}{\rho_F(\delta)\delta n})$ is strictly less than $\delta$. This essentially means that a non-uniform signal with sparsity factors $P_1$ and $P_2$ over the sets $\mathcal{K}'$ and $\mathcal{K}''$ is highly probable to be recovered successfully via the weighted $\ell_1$-minimization with weights $W_1$ and $W_2$. For any such $P_1$ and $P_2$, the signal parameters $(\delta, a_1)$ can be adjusted accordingly. Eventually, we will be able to recover signals with average sparsity factor $P_1 \gamma_1 + P_2 \gamma_2$ using this method. We simply plot this ratio as a function of $P_1$ in Figure 1. The straight line is the weak bound of [1] for $\delta = 0.555$ which is basically $\rho_F(\delta)\delta$.

![Fig. 1. Recoverable sparsity factor for $\delta = 0.555$, when the modified re-weighted $\ell_1$-minimization algorithm is used. $k_{total}$ on the vertical axis has been normalized with respect to $n$.](image)
