ABSTRACT

The aim of the present contribution is to extend the algorithm introduced in the paper S. Fiori and T. Tanaka, “An algorithm to compute averages on matrix Lie groups,” IEEE Transactions on Signal Processing, Vol. 57, No. 12, pp. 4734 – 4743, December 2009, to compute averages over the Stiefel manifold. The idea underlying the developed algorithms is that points on the Stiefel manifold are mapped onto a tangent space, where the average is taken, and then the average point on the tangent space is projected back to the Stiefel manifold. Based on this idea, a fixed-point algorithm is developed, and numerical examples are shown to support the analysis.

Index Terms—Matrix manifolds, Averaging on matrix manifolds, Manifold retraction, QR-decomposition.

1. INTRODUCTION

Representations involving structured matrices, such as orthogonal, symmetric and unitary matrices, arise frequently in signal processing. Well-known examples are Principal Component Analysis (PCA) and Independent Component Analysis (ICA) by signal pre-whitening [3]. Moreover, in statistical data processing, the data may appear under the form of random structured matrices (see, e.g., [4]). Random matrix theory is an important and active research area and it finds applications in wireless communication, compressed sensing and information theory. For example, in the last decades, a considerable amount of work has emerged in information theory on the fundamental limits of communication channels that makes use of results in random matrix theory [8]. A useful statistical characterization of a set of structured data-matrices is their empirical mean, which appears as an average matrix carrying on the same structure of the data themselves. Averaging over a data-set is a good method to smooth-out data and to alleviate measurement errors.

In case of unconstrained data, such as, for example, in the case that the matrix-type data belong to the flat space $\mathbb{R}^{n \times n}$, simple arithmetic averaging produces the desired result. However, in the case that constraints – such as orthogonality – are to be taken into account, arithmetic averaging does not produce a consistent result (this is due to the fact that, for example, the entry-by-entry addition of two orthogonal matrices is not orthogonal, in general). Therefore, to compute averages of structured matrices, it is necessary to build-up an averaging algorithm that takes into account the geometric features of the (generally curved) space that those matrices belong to.

Fiori and Tanaka [5] presented a general-purpose averaging algorithm that works for Lie groups and, in particular, for the space of special orthogonal matrices, that are square matrices with mutually orthogonal unitary-norm columns and such that their determinant is positive (namely, they represent high-dimensional rotations). A Lie group $G$ is an algebraic group with a manifold structure compatible with the algebraic structure. The algebraic structure is made of a set equipped with the general structure of the algebraic groups (namely, a multiplication operation, an inversion operation and an identity element). The differential-geometric structure manifests itself through the Lie algebra $\mathfrak{g}$, which is a vector space given by the tangent space to the manifold at the identity of the group. The method presented in [5] exploits the relationship between a Lie group and its associate Lie algebra and can be described as follows, with reference to Figure 1:

- The first step is to perform a left-translation $\ell_x$ of each sample $x_k \in G$ to a neighbourhood of the identity element $e$ of the Lie group.
- The next step is to map all samples onto the Lie algebra $\mathfrak{g}$, via a function $P_{x}^{-1}$, and to compute their arithmetic mean denoted by $\overline{x}$.
- The final step consists into mapping the Lie-algebra element $\overline{x}$ onto $G$ by a function $F_{\overline{x}}$ and into getting the mean element $x$ by the inverse left-translation $\ell_{x}^{-1}$.

Although there is a connection between the method proposed in [5] and the notion of Riemannian mean or Karcher mean
Fig. 1. Illustration of the averaging algorithm on the Lie group $G$ proposed in [5]. The dots (•) denote sample matrices and the box symbol (□) denotes the empirical average matrix.

[6], the substantial difference is that the Riemannian mean is defined on the basis of a least-mean dispersion criterion that involves the Riemannian (or geodesic) distance between two points, while the method proposed in [5] does not involve any metrics and is hence more general, in this regard.

Averaging on non-Lie-group-type manifolds is a substantially more involved problem. It could be tackled as a Riemannian-mean or Karcher-mean computation problem, but in some cases a distance function on manifolds of interest may be unavailable in closed form. In particular, there appear to be no reports about the problem of averaging on the Stiefel manifold (the space of orthogonal rectangular ‘tall-skinny’ matrices), which is not a Lie group, although a number of signal-processing applications requires statistical computation over the Stiefel manifold, such as data clustering [2], image and video-based recognition [9] as well as Bayesian filtering [7].

The aim of the present paper is to extend the algorithm introduced in the paper [5] to compute averages over the compact Stiefel manifold. The idea behind the developed algorithms is that points on the Stiefel manifold are mapped onto a tangent space, where the average over mapped points is taken, and then the average point on the tangent space is projected back to the Stiefel manifold. Most of the effort concerns the individuation of an appropriate retraction map for the Stiefel manifold and in the computation of its inverse.

2. AN AVERAGING ALGORITHM ON THE COMPACT STIEFEL MANIFOLD

The compact Stiefel manifold defined by:

$$\text{St}(p, n) \triangleq \{ X \in \mathbb{R}^{p \times n} | X^T X = I_n \},$$

where $I_n$ is a $n \times n$ identity matrix and $n < p$, namely, the manifold $\text{St}(p, n)$ is the space of the ‘tall-skinny’ orthogonal matrices. Its tangent space at a point $X \in \text{St}(p, n)$ may be expressed as $T_X \text{St}(p, n) = \{ V \in \mathbb{R}^{p \times n} | X^T V + V^T X = 0 \}$. A retraction map at a point $X \in \text{St}(p, n)$ is a map $P_X : T_X \text{St}(p, n) \to \text{St}(p, n)$. An inverse map of a retraction is termed lifting map and is denoted by $P_X^{-1} : \text{St}(p, n) \to T_X \text{St}(p, n)$. An inverse retraction is defined only locally, in general. Note that the inverse of a retraction map is not unique, in general. In this section, an averaging method on the Stiefel manifold based on the notion of retraction is presented. In particular, the proposed method is based on a fixed-point algorithm.

2.1. A retraction map and its associated lifting map on the compact Stiefel manifold

In [1], it is shown that one of the retractions $P_X$ that map a point of $T_X \text{St}(p, n)$ onto $\text{St}(p, n)$ is given by:

$$P_X(V) \triangleq qf(X + V)$$

where the quantity $qf(X + V)$ denotes the Q-factor of the thin QR decomposition of the matrix $X + V \in \mathbb{R}^{p \times n}$ and the R-factor is a upper-triangular matrix with strictly positive elements on its main diagonal, so that the decomposition is unique. The lifting map $P_X^{-1}$ can be represented by:

$$P_X^{-1}(Q) = QR - X,$$

where $X, Q \in \text{St}(p, n)$ are given and $R$ is an upper-triangular matrix with strictly positive elements on its main diagonal. Given matrices $X, Q \in \text{St}(p, n)$ if there exists an upper-triangular matrix with strictly positive elements on its main diagonal $R$ such that $QR - X \in T_X \text{St}(p, n)$, then the lifting map (3) exists. The matrix $R$ must satisfy the condition:

$$X^T (QR - X) + (QR - X)^T X = 0.$$

Namely, the matrix $R$ may be calculated by solving the linear system of $\frac{n(n+1)}{2}$ equations $(X^T Q)R + R^T (X^T Q)^T = 2I_n$.

2.2. A fixed-point averaging algorithm on the compact Stiefel manifold

Denote the sample matrices to average as $X_k \in \text{St}(p, n)$, with $k \in \{1, \ldots, N\}$, and assume that the samples $X_k$ are distributed in a neighbourhood of a center of mass $C \in \text{St}(p, n)$. The following considerations lead to an equation characterizing the empirical mean matrix:

- The first step is to map the points $X_k \in \text{St}(p, n)$ in a neighbourhood of the sought-for mean-matrix $X \in \text{St}(p, n)$ onto $T_X \text{St}(p, n)$ by a lifting map. Such points are denoted as $V_k \triangleq X_k R_k - X$. 

Fig. 2. Getting an average matrix by utilizing a Stiefel-manifold retraction. The dots (•) denote sample matrices and the box symbol (□) denotes their empirical mean-Stiefel-

- The second step is to compute the mean vector $\mathbf{V} = N^{-1} \sum_{k=1}^{N} V_k$, according to an arithmetic-average rule.
- The last step is to bring back the mean vector $\mathbf{V}$ to $\text{St}(p, n)$ by the retraction map and to get a mean matrix $X = q\bar{f}(X + \mathbf{V})$.

Such a procedure is illustrated in Figure 2. Summarizing the above procedure, a mean matrix $X \in \text{St}(p, n)$ is the solution of the matrix-type equation:

$$X = q\bar{f} \left( X + \frac{1}{N} \sum_{k=1}^{N} (X_k R_k - X) \right) \quad (5)$$

in the variable $X$. (Note that the matrices $R_k$ depend on the matrix $X$ via the condition $X_k R_k - X \in T_X \text{St}(p, n)$.) In general, however, the equation (5) cannot be solved in closed form. It may be solved by means of a fixed-point iteration algorithm, that generates a sequence $X^{(i)} \in \text{St}(p, n)$ of estimates converging to the sought-for empirical mean matrix $X$, and that may be written as:

$$X^{(i+1)} = q\bar{f} \left( \frac{1}{N} \sum_{k=1}^{N} X_k R_k (X^{(i)}) \right), \quad i \geq 0, \quad (6)$$

where the matrix $X^{(0)} \in \text{St}(p, n)$ denotes an initial guess and the notation $R_k(X^{(i)})$ emphasizes the fact that the upper-triangular matrix $R_k$ depends on the current estimate $X^{(i)}$ via the condition (4).

3. NUMERICAL RESULTS

The first experiment refers to the case of averaging over the manifold $\text{St}(4, 3)$. In such an experiment, three different sets of samples of different cardinality $N$ were generated. The data-sets were generated around a common center of mass $C \in \text{St}(4, 3)$ and the averaging algorithm (6) is always initialized to the same point $X^{(0)}$. The data-sets count $N = 10$, $N = 50$ and $N = 200$ samples, respectively. In the following, the measure of discrepancy $\delta: \text{St}(p, n) \times \text{St}(p, n) \to \mathbb{R}_{+}$ between two Stiefel-manifold matrices, defined as $\delta(C, X) \overset{\text{def}}{=} \| I_n - X^T Y \|_F$, where $\| \cdot \|_F$ denotes Frobenius norm, is made use of. The obtained curves, in term of discrepancy $\delta(C, X^{(n)})$, are shown in the Figure 3.

The figure shows that the algorithm converges steadily and in a few iterations and, as the available information becomes richer, the accuracy of the estimate improves.

The second set of experimental results concerns the problem of averaging over the manifolds $\text{St}(4, 3)$, $\text{St}(30, 3)$, $\text{St}(20, 5)$ and $\text{St}(20, 8)$ by keeping fixed the cardinality of the data-set. The Figure 4 illustrates the obtained results, again in terms of discrepancy $\delta(C, X^{(n)})$, which show that by keeping $p$ fixed and increasing $n$, the convergence becomes more difficult, and the same happens when $n$ is kept fixed and $p$ increases. Yet the developed algorithm can cope with relatively large-size problems.

The third experimental result refers to the case of averaging real-world samples over the manifold $\text{St}(5, 3)$. The $N = 50$ samples $X_k \in \text{St}(5, 3)$ to average were obtained by running a fastICA algorithm [3], which separates out 3 independent source signals from 5 mixtures, on 50 independent trials on the same separation problem. The Figure 5 illustrates the obtained results, expressed in terms of separation performance index (PI) [3]. The figure shows that the value of the PI corresponding to the empirical average matrix $X \in \text{St}(5, 3)$
collocates in an average position with respect to the PI values of the single patterns $X_k \in \text{St}(5, 3)$.

4. CONCLUSIONS

The present paper extends the algorithm introduced in [5] to compute averages over Lie groups to the Stiefel manifold. The present method inherits the main advantage of the previous method, namely, it does not involve any metrics and is hence more general than the Riemannian mean method. The numerical results show that the algorithm converges steadily and in a few iterations and can cope with relatively large-size problems.

A thorough analysis of the possible retraction/lifting pairs that may be associated to the Stiefel manifold, along with their numerical implementation features, is being conducted and will be presented in a forthcoming longer report.
